New species of fossil nonmarine molluscs from Western Australia and evidence of late Quaternary climatic change in the Shark Bay district

by George W. Kendrick

Western Australian Museum, Francis Street, Perth, W.A. 6000

Manuscript received 21 June, 1977; accepted 21 June, 1977.

Abstract

The new species Coxiella roae sp. nov. (Prosobranchia: Hydrobiidae), Bothriembryon gardneri sp. nov., B. consors sp. nov., B. douglasi sp. nov. and B. ridei sp. nov. (Styliommatophora: Bullimulidae) are described and figured. All occurrences are believed to be of Pleistocene age.

Coxiella roae sp. nov. was obtained from lacustrine deposits in the Beermullah district and represents the first fossil species to be recorded for the genus.

The four new species of Bothriembryon snails come from fossil soils in the Point d'Entrecasteaux and Shark Bay districts. Those from the former locality, B. gardneri sp. nov. and B. consors sp. nov., are related ancestrally to living species. The two Shark Bay species, B. douglasi sp. nov. and B. ridei sp. nov., have no known living descendants. Their extinction, and the apparent subsequent appearance of caenomelids in the district, are interpreted as evidence of a period of severe regional aridity during the late Pleistocene.

Systematic descriptions

Class Gastropoda
Subclass Prosobranchia
Order Mesogastropoda
Superfamily Rissiooidea
Family Hydrobiidae

Genus Coxiella E. A. Smith, 1894.

Type species (by original designation): Truncatella striatula Menke.

From consideration of the shell characters, Coxiella has been referred to a diversity of families, e.g., Hydrobiidae subfamily Truncatellinae (Thiele, 1931; Macpherson, 1957), Coxiellidae (Tredale, 1943), Truncatellidae (Cotton, 1959; McMichael, 1967) and Assimineidae (Ludbrook, 1956). Living animals of C. striatula have been examined by Dr. G. M. Davis of Philadelphia who states (pers. comm., May 1972) that, in characters of the head-foot morphology, mode of progression, form of the eyes and tentacles and the radula, they show affinity with the Hydrobiidae and not the Truncatellidae; clarification of the subfamily position requires further study.

Introduction

This paper describes five new species of molluscs, one freshwater and four terrestrial, from the fossil collections of the Western Australian Museum (WAM) and the Field Museum of Natural History, Chicago (FMNH). The material studied came from three widely separated areas in southwestern Australia (Fig. 1).

Coxiella roae sp. nov. was obtained in sediments collected from wells, seismic boreholes and other shallow excavations in the Beermullah district, 80 km north of Perth, by Mrs. R. Roe, of "Benalong", Beermullah.

From 1941 to 1976, fossil snail shells have been obtained by a number of collectors from exposures, both natural and man-made, of lithified fossil soils associated with aeolian calccarenite at Point d'Entrecasteaux on the coast of western Australia south-southeast of the town of Northcliffe. The deposit contains at least eight different species of land snails, of which two, Bothriembryon gardneri sp. nov. and B. consors sp. nov., are described below.

Collections of land snails from widely dispersed fossil soils in the Shark Bay district, resembling the Depuch Formation, have been found to contain two species of Bothriembryon distinct from any now living. These species, which appear to be allopatric, are described as B. douglasi sp. nov. and B. ridei sp. nov.

A comparison of what is known of modern and fossil land snail distributions in the Shark Bay district suggests that a period of glacial-climatic low sea levels during the late Pleistocene was marked by the extinction of two Bothriembryon species and the subsequent local establishment of up to four species of arid-adapted caenomelids. These apparent faunal changes are considered to reflect a regional climatic shift towards increased aridity. A relative climatic amelioration appears to have eventuated in the wake of the Flandrian (Holocene) transgression, possibly reflecting the strengthening of maritime influences in the area.

Systematic descriptions

Class Gastropoda
Subclass Prosobranchia
Order Mesogastropoda
Superfamily Rissioidea
Family Hydrobiidae

Genus Coxiella E. A. Smith, 1894.

Type species (by original designation): Truncatella striatula Menke.
Material. Holotype WAM 73.4. Paratypes WAM 73.5 (40 shells). Other topotypic reference material WAM 73.6, 73.7, 73.8, 73.9 (560 shells). All of this material was collected originally as a single sample.

Type locality. Beermullah, Western Australia. Lat. 31° 11'S, long. 115° 42'E. "Benalong" bore at northern part of Swan Location 3261, about 0.5 km east of Location 2880, ("Pin Pin"); 4.6-4.9 m below ground surface (Fig. 2).

Diagnosis. A medium-sized Coxiella up to 17 mm high, of somewhat variable form, elongate-conical or turriculate, with height about twice the maximum diameter. Protoconch smooth, paucispiral, either present or absent through decollation, in which case a septum is formed. Whorls convexly rounded, flattened, shouldered or carinate; sometimes cingulate above the periphery, with sutures impressed or incised. Sculpture of irregular, colabral growth rugae and very fine, close, spiral striae, becoming obsolete on the base and occasionally entirely absent. Umbilicus present, small in juveniles, becoming wide (for the genus) in mature shells. Aperture ovate to quadrature, according to the degree of carination; often with persistent yellow-brown pigmentation within. Shells white externally.

Description of holotype. Shell of medium size, elongate-conical, of 7.8 whorls in a height of 9.6 mm, maximum diameter 5.5 mm. Apex intact, protoconch smooth, paucispiral; spine whorls convexly rounded, the last whorl slightly flattened, sutures impressed. Sculpture of irregular, colabral growth rugae and very fine, close, spiral striae, becoming obsolete on the base. Umbilicus open, small. Aperture ovate, oblique and continuous, the colabral lip everted; faintly yellow-brown within. Shell white externally.

Observations. Of the described species of Coxiella, (Macpherson 1957), the fossil species is closest in general shell proportions to C. pyrrhostoma (Cox), though not attaining the height of that species (17 against 20 mm). Other similarities are the presence of contrasting pigmentation within the aperture and the spiral striation. Some rugose, shouldered or cingulate shells of roeae recall specimens of C. glauerti Macpherson from the Esperance-Israelite Bay district. Examination of a range of specimens from that area collected since Macpherson's revision of the genus suggests to the writer that glauerti may be no more than a localised geographic form of pyrrhostoma.

C. roeae differs markedly from pyrrhostoma and most other species of Coxiella in the relatively late onset of decollation and also in the limited extent to which this is usually manifested. This is shown among the fossils by the presence of a substantial proportion of mature shells having either intact or very slightly decollate apices. In pyrrhostoma by contrast, decollation appears to occur early in growth when the shell is 4.5 mm high and recurs subsequently a number of times. Juvenile, non-decollate shells of pyrrhostoma have a subcylindrical form in contrast to the ovate-conical form of young roeae. Occasional shells of roeae exhibit a more extensive decollation, comparable to that of extant species. Carination of the whorls in a proportion of shells distinguishes roeae from all other congens. The new species is considerably more variable in shell characters than any other Coxiella; however the extreme forms are connected by intermediates and all are considered to represent a single species. The paratype series, a selection of which is illustrated (Fig. 2C-N), demonstrates this variation.

The carinate forms of C. roeae bear a remarkable resemblance to shells of Pyrgula barroisi Dautzenberg (Truncatellidae) from the Sea of Galilee, figured by Tchernov (1975, p. 156, Figs. 5, 6, 9).

The species is named after Mrs. R. Roe, who presented to the Western Australian Museum all of the material and collecting data utilised in this study.

Geographic range. The present species has been collected by Mrs. Roe from spoil from a series of bores, wells, seismic shotholes and other shallow excavations within 12 km to the south and east of the type locality and from a surface outcrop on the eastern side of Beermullah Lake some 8.5 km to the east. The positions
of these localities are shown in Fig. 2; the greatest depth sampled was 13.7 m below the ground surface. Hosking and Greave (1936, p. 106) report "hard compact limestone containing small mollusc shells of presumably Tertiary age" from near "Glencoe" homestead, Beermullah. This property, now known as "Mirilla", lies about 8 km southeast of known occurrences of C. roeae and may contain an extension of the same Coxiella beds. The data suggest that one or more extensive lakes may have occupied the area at the time of deposition. The presence of occasional associated fossil shells of the pond snail genera Physastra and Gyraulus (e.g. WAM 73.10, 71.984) with C. roeae indicates that these water bodies were more likely to have been fresh rather than saline at the time of deposition.

Stratigraphic range. The precise age of the present material cannot as yet be determined but marine mollusc shells (WAM 73.98-104, 73.106-7) from a bore on Swan Location 2680 ("Pin Pin", Fig. 2), close to the type locality of C. roeae but from between 27.4-36.6 m below the ground surface are, in the writer's view, of probable Pliocene age. If so, then the overlying lacustrine beds containing C. roeae were probably laid down during the Pleistocene. Apart from late Quaternary deposits around Lake Eyre, South Australia, containing fossils of the extant C. gilesi (Angas) (Ludbrook 1956; King 1956), little has been established of the geologic history of the genus.

Subclass Euthyneura
Order Stylommatophora
Superfamily Bulimulacea
Family Bulimulidae

Genus Bothriembryon Pilsbry, 1894.
Bothriembryon Pilsbry; Kendrick and Wilson, 1975.

Type species (by original designation): Bulimus melo (Quoy and Gaimard) = Helix melo Quoy and Gaimard.

Bothriembryon gardneri sp. nov.
(Fig. 4, A-E)

Material. Holotype WAM 70.1603a. Paratypes WAM 70.1603b and c, 2 shells; 66.794a and b, 2 shells embedded in a laminar piece of brown calcarenite; 66.796a, h and w, 3 shells; FMNH 194694/3, 3 shells. Other reference material WAM 70.1603d to p, 13 topotypes; 66.795, 1 shell in hard, brown calcarenite; 66.796, 2 shells in hard, brown calcarenite; 66.797, 2 shells in a large, laminar piece of brown calcarenite; 66.798, 18 complete and 31 fragmentary shells; 62.196, 1 shell in brown calcarenite; 62.197, 1
Figure 3.—Coxiella rocae sp. nov. A, B—Holotype, WAM 73.4. C—N.—Paratypes, 73.5 a-f. All x 3.
shell filled with brown calcarenite; 65.33, 2 shells; 65.34, 3 shells; 65.480, 1 shell; 70.900, 10 shells; 72.420, 32 shells; 73.253, 1 deformed shell, probably of this species; 73.254, 1 shell; 75.860, 2 shells; 9881, 2 shells in brown calcarenite: FMNH 182299, 7 shells.

**Type locality.** Point d'Entrecasteaux, Western Australia. Shallow quarry on crest of low ridge of calcarenite on north side of track from Windy Harbour to Salmon Beach. The site is located 3.5 km on a bearing of 32° from the Point d'Entrecasteaux lighthouse. Lat. 34°49'14"S, Long. 116°00'52"E (Fig. 5).

**Diagnosis.** A large, robust Bothriembryon, elongate-ovate, up to 45 mm high, with a height usually greater than twice the maximum diameter and spine height more than half the total height. Whorls convex, about 5.7 in a height of 40 mm, sculpture of strong, colabral growth rugae, generally without spiral granulation. Protoconch of 2.1-2.3 slightly convex whorls, dome-shaped; sculpture fine, mainly reticulate over the first 1.5 whorls and tending to become axially aligned or wrinkled over the abapical portion, where weak axial rugae may also develop. Traces of whitish axial flames are sometimes apparent on the abapical portion of the protoconch.

**Description of holotype.** Shell large, robust, of 6 whorls in a height of 43.5 mm, maximum diameter 19.5 mm, height of spire 24 mm. Whorls convex, suture impressed and lightly crenulated; sculpture of colabral growth rugae, concentrated below the suture; spiral sculpture absent. Umbilical fissure small. Parietal callus thick, colu-mella concave, thick and reflected. Protoconch dome-shaped, of 2.1 whorls, bearing a fine axially-reticulate sculpture, which becomes progressively more axial on the abapical portion, where weak axial rugae, anticipating the teleoconch sculpture, also appear. The cavity of the shell contains a friable, cream calcarenite.

**Observations.** Of the described species of Bothriembryon from Western Australia (Ireland 1939), B. gardneri most resembles B. fuscus Thiele from the south coastal Karri forests between Torbay and Walpole. In the shape, size and sculpture of the protoconch, the two species are quite similar; furthermore in each a weak axial flame pattern can be detected occasionally.
on the abapical extremity of the protoconch. The two species differ essentially in features of the teleoconch. The fossil species has a rather more elongate shell than fusca: though attaining a slightly greater height than the living species (45 mm against 43 mm), gardneri does not reach the maximum width of fusca (19.5 mm against 21 mm). The spire height of mature shells of gardneri invariably exceeds the aperture height, whereas in fusca these dimensions are about equal, as Iredale noted. In details of the sculpture, the two species also differ. Axial growth rugae are much stronger in gardneri and spiral granulation is generally absent; traces of this feature may be detected under magnification on an occasional shell. Fine spiral granulation and (sometimes) striation ornament the spire whorls of fusca. These occur on the shell proper and are not mere periostracal features. A Field Museum paratype from the Pt. d'Entrecasteaux cliff near the lighthouse shows traces of a wide, axial flame pattern on the teleoconch, such as occurs on some shells of fusca.

This comparison of B. gardneri and B. fusca shows that the two share a range of common characters and probably are closely related. Possibly the former stands in an ancestral position to the latter. If so, then the direction of morphologic change has tended toward a shorter, more ovate shell with fine spiral granulation in lieu of strong axial rugae. The presumably non-adaptive protoconch characters have remained unaltered over this time.

Fossil snails associated with B. gardneri include two congeners, one of which, B. consors sp. nov., is described below, as well as species of Paralaoma, and Magilaoma (Punctidae), Pernagera and one other charopid (Charopidae) and an undescribed assimineid (A. Solem, pers. comm., Sept. 1976). This assemblage suggests a humid, well-vegetated, probably forested environment at Point d'Entrecasteaux at the time of deposition, in contrast to the exposed coastal heath that presently characterizes the area. This species is named after Mr. G. D'Entrecasteaux of Northcliffe, who introduced the author to the type locality and assisted in the collection of the type material.

Geographic range. Bothriembryon gardneri is known only from the type and adjacent localities at Point d'Entrecasteaux, within 4 km of the lighthouse (Fig. 5). The material has been collected from natural and man-made exposures of fossil soils occurring on and beneath the surface of an elevated ridge of aeolian calcarenite, now truncated by a prominent sea cliff.

Stratigraphic range. No direct evidence of age for the calcarenite deposits at Point d'Entrecasteaux is available but, by analogy with similar formations in south-western Australia (Lowry 1967), a Pleistocene age is assumed. The uppermost fossil soil, containing abundant land snail shells, is generally well lithified and underlies a thin, brown, surface (possible deflated) quartz sand. A Pleistocene age for the fossils appears probable.

Bothriembryon consors sp. nov.

(Fig. 4, F, H)

Material. Holotype WAM 72.421a. Paratypes WAM 72.421b to e, j and k, 6 shells; 70.901a and b, 2 shells; 70.1602d, 1 shell. Other reference material WAM 70.1602a to c, e to g, i to m, o to q, 14 shells.

Type locality. Windy Harbour, Western Australia. Shallow quarry NE of lighthouse beside track to Salmon Beach. The site is located 3.5 km on a bearing of 32° from the Point d'Entrecasteaux lighthouse. Lat. 34° 49' 14" S, long. 116° 00' 52" E (Fig. 5). This is the same place as the type locality of Bothriembryon gardneri, cited above.

Diagnosis. A medium-sized, robust Bothriembryon, elongate, up to 32 mm high, with a height about 2.1 times the maximum diameter; spire height slightly more than half the total height. Whorls gently convex, about 5.5 in a height of 30 mm; sculpture of fine, close, colabral growth lines crossed by fine spiral granulation, concentrated below the suture and becoming obsolete on the last whorl. Traces of narrow, brown and white axial striping are visible on some shells. Protoconch of 1.9 to 2.2 whorls, elevated, somewhat tumid, sculpture finely punctate with or without a weak axial alignment and becoming very finely axially wrinkled on the abapical extremity; pale axial flames present on the second whorl.

Description of holotype. Shell medium-sized, elongate, of 5.3 whorls in a height of 29.9 mm, maximum diameter 13.8 mm, height of spire 16.9 mm. Whorls gently convex, suture impressed and finely crenulated; sculpture of fine, close, colabral growth lines crossed by fine spiral granulation, concentrated below the suture and becoming obsolete on the last whorl. Columella slightly concave and reflected over a minute umbilical fissure. The teleoconch retains faded, narrow, brown and white axial striping. Protoconch elevated, slightly tumid, of 2.1 convex whorls bearing fine reticulate-punctate sculpture, which becomes axially wrinkled near the
abapical extremity; pale axial flames present on
the second whorl. The cavity of the shell con-
tains a friable, cream calcarenite.

**Observations.** From the combination of
an attenuate shell, axially striped and with weak
spiral granulation and a protoconch patterned
with axial flames, it appears that the affinities of
*Bothriembryon consors* lie with a group of
species from south coastal districts typified by
*B. kingii* (Gray). Shells of this general form
occur from the vicinity of East Mt Barren west-
towards the Meerup River some 20 km north of
Point d’Entrecasteaux, being represented by the
species *maxieli* Kobelt, *jacksoni* Iredale,
*notatus* Iredale as well as *kingii*. The field
relationships and precise differentiation of these
species await clarification but examination of a
range of recently collected material in the
Western Australian Museum suggests that there
is much intergradation in shell characters.

Whether they represent different, wide-ranging, vari-
able species or several has yet to be demon-
strated conclusively, but despite a generalised
resemblance, the fossil species, *consors*, does not
closely correspond to shells from any part of
this series. Such similarities as can be seen are
more noticeable with the attenuate shells
that occur from Albany eastward and least of
all with the wide, ovate shells that characterise
the western end of the series.

In the ratio of height to maximum diameter
*consors* resembles shells of the type popula-
tion of *B. kingii* from Albany, but differs in other
characters. The fossil attains 5.5 whorls in a
height of 30 mm, whereas *kingii* reaches only
about 22 mm for this degree of coiling. The
protoconch of *consors* is larger, more through-
more finely sculptured and shows less axial
alignment of the sculpture than typical *kingii*.

Shells of *B. jacksoni* from the Walpole-Nornalup
National Park are relatively wide with a height:
maximum diameter ratio of 1.8:1, attaining 5.5
whorls in 27 mm; protoconch sculpture tends to
be closer to that of *consors* than *kingii* but
the teleoconch characters diverge markedly.

Throughout the entire modern *kingii* series, the
shells tend to be thin and fragile, even where
obtained from calcareous coastal soils. By con-
trast, the shells of *consors* are all robust, some
exceptionally so. This contrast between the two
species applies to specimens from similar sub-
strates and may reveal more than a simple
ephelpean response. The differences in shell
characters between *consors* and the modern
*kingii* series (sensu lato) indicate that the group
has undergone some morphologic divergence
within the Quaternary. This may have been
greater in the western part of the range, with
the development of a wider, ovate form of shell.
An overall trend within the group seems to have
been the evolution of a relatively thin shell.

*B. gardneri* and *B. consors* contrast strongly
in characters of the teleoconch. The former
and larger species has about 5.7 whorls in a
height of 40 mm, the latter about 5.5 spirally
granose whorls in only 30 mm. The protoconchs
of the two species differ in the number of whorls,
degree of elevation, sculpture and pattern.

**Geographic range.** *Bothriembryon consors*
is known only from the type and adjacent loca-
tilities at Windy Harbour (= Point d’Entrecasteaux)
within 4 km of the lighthouse (Fig. 5). The
localities parallel those for *B. gardneri*, both
species occurring together in the same fossil
habitats at Point d’Entrecasteaux. The name
*consors* alludes to this association.

**Stratigraphic range.** As for *B. gardneri*, prob-
ably Pleistocene.

---

**Bothriembryon douglasi** sp. nov. (Fig. 6, A-E)

**Material.** Holotype WAM 66.1036a. Paratypes
WAM 66.1036b, c, 2 shells; 68.1434c, d, g, j and
0, 5 shells. Other reference material, WAM
66.1036d to f, 3 shells; 68.1434a, b, e, f, h, i, k
to n, 10 shells.

**Type locality.** Sea cliff at the Carrarang-
Tamala boundary fence, Edel Land, Shark
Bay, Western Australia. Lat. 26° 32’ 26” S, long.
113° 26’ 42” E; from within the top 7.5 m of the
cave (Fig. 7).

**Diagnosis.** A large *Bothriembryon*, ovate-
conical, up to 35 mm high, height about 1.7
times the maximum diameter and attaining
about 5.5 whorls in a height of 27 mm. Spire
about half the total height or less; sculpture
of fine, irregular growth lines crossed above
the periphery by weak spiral granulation. Culo-
mella thin; umbilicus small, open. Protoconch
bluntly rounded, of 2.1 to 2.4 wide, convex
whorls, sculptured with fine, close irregular axial
wrinkles. Protoconch apparently of one colour,
slightly darker than the teleoconch.

**Description of holotype.** Shell large, ovate-
conical, of 6.0 whorls in a height of 34.2 mm,
maximum diameter 19.6 mm, height of spire
17.0 mm. Whorls convex, suture impressed and
edged with a weak groove, base evenly rounded;
spire of growth lines crossed above the perip-
ery with fine, spiral granulation. Columella
thin, reflected, partly obscured by matrix; umbi-
icus small. Protoconch of 2.1 whorls, rather
worn but retaining traces of fine, close axial
wrinkling; slightly darker than the teleoconch.
The type is a dull-white, somewhat worn shell,
cracked on the spire and lacking small sections
of the outer layer in several places; the exterior
carries some thin, pale-brown calcarete and the
cavity is filled with a hard, pale-brown quartz-
ose calcarenite.

**Observations.** In the form of the teleoconch
and the sculpture and deeper shading of the
protoconch, only one species, *B. distinctus* Ired-
dale from the Balladonia district (Iredale 1939)
shows any significant resemblance to *B. dou-
glasi*. The similarity is less obvious with larger
fossils, such as the type of *douglasi*, but more so
with smaller shells, such as those from the
"Zuytdorp" locality (Fig. 7), which are about
the same size as mature specimens of *distinctus*.
Spiral granulation on the teleoconch is a little
stronger in *distinctus* and there is a size dif-
ference in the protoconch; that of *douglasi*
ranges from 2.1 to 2.4 whorls, *distinctus* from
1.7 to 2.1 whorls. These differences, together
with the remoteness of the two geographic ranges (over 1,000 km apart) suggest that the two species have been differentiated for an appreciable time.

At the type locality, the new species is associated with fossils of *B. costulatus* (Lamarck) (WAM 66.1037); a shell, probably also of Lamarck's species has been collected from a fossil soil at the "Zuytdorp" site (WAM 68.563) (Kendrick and Wilson 1975).

The new species is named after Mr. A. M. Douglas, who collected the specimens from the "Zuytdorp" locality, employed in this description.

**Geographic range.** Bothriembryon douglasi is known only from the type locality and from a similar position on the coastal cliffs at the site of the "Zuytdorp" wreck, 70 km further south.

**Stratigraphic range.** At both of the known localities, shells of *B. douglasi* occur in fossil soils similar to the Depuch Formation of the Shark Bay district (Logan et al. 1970). Specimens are associated with brown, quartzose, calcarenites; some from the type locality also bear thin, hard crusts of light brown calcrete. A Pleistocene age seems probable for these lithified fossil soils.

**Bothriembryon ridei** sp. nov. (Fig. 6, F, H)

**Material.** Holotype WAM 60.434a. Paratypes WAM 60.434b, d, e, 3 shells; 66.660a, 74.531a. Other reference material WAM 60.434c, e to p, 13 shells; 65.1158, 1 shell; 66.660b to 1, 11 shells; 66.675, 1 shell; 69.1207a to d, 4 shells; 70.1869a, b, 2 shells; 74.531b to h, 7 shells.

**Type locality.** Western side of Dorre Island, Western Australia; limestone cliffs opposite Disaster Cove. Lat. 24° 59' 52" S, long. 113° 07' 12" E (Fig. 7).

**Diagnosis.** A large Bothriembryon, ovate-conical, ventricose, up to 40 mm high, height about 1.5 times the maximum diameter and attaining about 6 whorls in a height of 38 mm. Spire less than half the total height; sculpture of fine growth lines with weak spiral granulation present above the periphery but becoming obsolete on the last whorl. Columella thin, umbilicus small. Protoconch of 1.8 to 2.1 whors,
low and wide, sculptured with axial reticulation. Protoconch apparently of one colour, tending to be darker than the teleoconch.

**Description of holotype.** Shell large, ovate-conical, ventricose, of 5.9 whors in a height of 36.3 mm, maximum diameter 22.7 mm, height of spire 16.0 mm. Whors convex, suture impressed; sculpture of fine growth lines crossed by weak spiral granulation above the periphery and becoming obsolete on the last whorl; base evenly rounded. Columella thin, reflected; umbilicus filled with sediment. Protoconch of 2.0 whors, low, wide, sculpture axially reticulate and strong; of one colour, slightly darker than the teleoconch. Like all the material to hand, the type is a dull white shell lacking other indication of the original colour. It is cracked in several places and part of the outer lip is missing. The cavity is filled with brown calcite.

**Observations.** In form and size, *B. ridei* most resembles shells of *B. dux* (Pfeiffer), from the south coast region of Western Australia between about Ongerup and Caiguna. The new species however has a more ventricose shell, on which the spiral granulation is stronger and does not attain the height of the other (*41 mm compared with 55 mm for dux*). The protoconchs of the two species are of similar size but that of *ridei* exhibits a stronger axial component in the sculpture, best exemplified by paratype 60.434e.

The new species is named after Dr W. D. L. Ride, who, whilst Director of the Western Australian Museum, collected the type series and other material of this species.

**Geographic range.** Occurrences of shells of the present species at the type locality are discussed by Ride (1962, p. 24, 25, pl. 11). Additional occurrences are: Western side of Dirk Hartog Island, 32 km north of the homestead, apparently weathered from the cliff; Bernier Island, eastern coast near Wedge Rock and western coast opposite Red Cliff Point; Quobba Point near "The Blowhole".

**Stratigraphic range.** The report of Ride (1962) and field data recorded on labels accompanying the above material indicate that *B. ridei* occurs in fossil soils resembling those of the Depuch Formation, overlying the Tamala Eolianite. (Logan et al., 1970). All specimens to hand are associated either with a dense, brown calcite or indurated quartzose calcarenite. A Pleistocene age seems probable.

**Late Quaternary climate in the Shark Bay district.**

A comparison of modern and (what is known of) fossil land snail distributions in the Shark Bay district reveals some apparent contrasts which deserve consideration. Assuming that *B. douglasi* and *B. ridei* were broadly contemporaneous, it would appear that, at some as yet undefined stage of the Pleistocene, three species of *Bothriembryon*, all relatively large-shelled, inhabited the district: *ridei* occurred across western and northern Shark Bay and *douglasi* occupied the Edel Land coast (Fig. 7). The
distributions of these two species seem to have been allopatric. The third species, *costulatus*, which is extant (Kendrick and Wilson 1975), coexisted with both fossil species but the shells tended to be larger than modern specimens. The largest known example of *costulatus* (WAM 66.1037g, 6.2 whorls in a height of 30.1 mm) is a fossil from the type locality of *douglasi*. The extinction of two of these species and the size-reduction of the third presumably resulted from adverse environmental change, probably increased aridity. Whether this size-reduction applied generally to *costulatus* throughout its range, or featured local extinction and subsequent replacement by selected morphs of reduced size from outside the immediate area, remains speculative. The latter hypothesis is supported by the presence of distinctive, large-shelled populations of *costulatus* inhabiting the littoral fringe between Point Cloates and Point Maud. A shell of this form, from near the northern end of the species’ range, was illustrated by Kendrick and Wilson (1975, Pl. IV, Fig. 11).

The Camaenidae, which incorporates the Chloritidae, Xanthomelontidae and Rhagadidae of Iredale (1939), are the principal family of land snails in arid Western Australia from Shark Bay northward, being particularly well developed in the Kimberley region (Wilson and Smith 1975). At least four species represent the family in the Shark Bay district; one in particular, *Rhagada torulus* (Perussac), is common on Bernier and Dorre Island and also occurs on Dirk Hartog Island and at Quobba and elsewhere on the mainland coast. Species of *Angasella* and *Plectorhagada* occur along the southern and south-eastern littoral and hinterland, while a *Plectorhagada* is present on Dorre Island. This group of snails is currently being studied by Dr A. Solem. Camaenid records are rare in west-coastal districts south of about latitude 27°, the peripheral occurrences in this region being *Angasella abstans* in the lower Murchison and Greenough districts (Iredale 1939 and G.W.K. unpublished notes). *A. abstans* appears to be a relict species with a strongly disjunct distribution, isolated from the main occurrences of the family. It may represent an earlier Pleistocene camaenid incursion into the northern fringe of the humid south-west. The family is absent from the south-western corner of the State, where *Bothriembryon* dominates the land-snail fauna.

No camaenid fossils have been found in association with either *B. douglasi* or *B. ridei*, despite the abundance of modern specimens, notably those of *Rhagada torulus*, at most of the known localities of the latter species (*ridei*). The few fossil records of camaenids from the

Shark Bay district (WAM 66.807, 73.85, 73.87) all appear to be of very recent geologic age. Significantly, all are associated with the diminutive, modern form of Bothriembryon costatus, for which Iredale (1939) employed the name B. minor Pilbry (Kendrick and Wilson 1975).

The evidence available from modern and fossil records suggests that the camaenid snails reached the Shark Bay district at some time after the extinction of B. douglasii and B. ridei. The demise of these two species and the size-reduction of B. costatus are seen as consequences of an environmental change toward greater aridity. It is assumed that the camaenids, being pre-adapted to the drier conditions prevailing in northern areas, would have been favoured by any such change and would have extended their ranges southward and westward into the Shark Bay area. It is noteworthy that camaenids closely related to Shark Bay species are at present living in the country between the Gascoyne River and Cape Range; these may represent the original stocks from which the Shark Bay camaenid populations originated.

The timing of these events cannot yet be established precisely but some inferences can be drawn from the distribution data. Camaenid populations on Bernier and Dorre Islands have been isolated from the mainland since the submergence of the Naturaliste and Geographe Channels during the Flandrian transgression of the sea, some 8,000 years ago (Morner 1971, p. 76). The bathymetry of South Passage between Dirk Hartog Island and the mainland indicates that severance of this island probably occurred a little later. Prior to this, the mainland connections of the Shark Bay "islands" would have been continuous for the entire duration of the last major glacio-eustatic regression of the sea, corresponding to the Wurm-Würmian glaciation of northern Europe. During this period of global cooling, which became fully assertive from about 80,000 year ago (Broecker and van Donk 1970, Emiliani 1972), sea level fell more than 100 m below its present position (van Andel et al. 1967). The camaenid occupation of the Shark Bay district, in particular of the western islands, probably occurred during this time. If so, it may be assumed tentatively that the extinction of Bothriembryon douglasii and B. ridei marked a transition from (relatively) humid to arid conditions beginning around 80,000 year ago (Fig. 8).

Evidence in support of relative aridity in low and middle latitudes accompanying the reduced global temperatures of the last major glaciation of the Late Pleistocene has been advanced from studies in northern and eastern Australia (van Andel et al. 1967; Bowler and Hamada 1971; Dodson 1975), in south-east Asia (Verstappen 1974), the equatorial Pacific (Quinn 1971), tropical South America (van der Hammen 1972) and, in a review of all continents by Williams (1975), indicating a general convergence of views in this direction. Investigations of late Pleistocene and fossil distributions of land snails in the Shark Bay district are consistent with such an interpretation.

Still to be considered is the history of B. onslowi (Cox), the second extant species of Bothriembryon in the Shark Bay district (Kendrick and Wilson 1975). Fossils to hand are few (WAM 66.278, 66.658, 66.668, 71.225), all being derived from modern soil profiles of young geologic age. A number of fossils include the diminutive, modern form of B. costatus but, as yet, no camaenids. The distribution of onslowi around southern Shark Bay, in Edel Land, on Peron Peninsula and Dirk Hartog Island (but not on Bernier or Dorre Islands) suggests that it entered the westernmost part of this range at a time when Dirk Hartog Island was joined to the mainland but when Bernier and Dorre Islands were not. As noted above, this would have been some time after 8,000 year ago. The living colours of B. onslowi are shades of a rather intense brown, matching the strongly coloured soils of Peron Peninsula and the south-eastern hinterland of Hamelin Pool. Well-developed cryptic coloration such as this supports the view that the species has had a relatively long association with areas of deeply coloured soils and, more recently, perhaps by Edel Land and Dirk Hartog Island, where soils are pallid.

Acknowledgements.—I have to thank Mrs R. Roe of Beermullah for the collection of specimens and the provision of field data; and Mr G. Gardner of Northcliffe for assistance in the field and generous hospitality. Dr A. Solem kindly made available material from the collection of the Field Museum of Natural History and advised with the identification of associated fossil snails. Colleagues at the Western Australian Museum critiqued the manuscript and suggested improvements. Maps were drawn by Mr P. M. Bradbury, and the photography done by Miss V. A. Ryland.
